for the degree of Doctor of Medicine
1979

ABSTRACT

Cigarette smoke has been implicated as a cause of intimal thickening in the small vessels of the myocardium. Renal vascular changes have never been shown to be associated with cigarette smoking. Evidence for the effect of smoking on the myocardium has been based on qualitative morphologic studies.

One section of myocardium and kidney from 25 smokers and 15 non-smokers was examined and each artery less than 600μ was photographed. Planimetric technique was used to calculate the ratio of intimal to whole vessel wall area. The average value per section was calculated as was the value for each arteriolar size class (greater or less than 150μ).

Smokers have greater intimal thickening than non-smokers in both myocardium and kidney ($P < 0.001$). This was true for all vessel sizes examined. Some age-related intimal thickening could be inferred but further investigation is necessary. All statistically insignificant results were analyzed by Type II error analysis to avoid inappropriate acceptance of the null hypothesis.

This is the first study to show a smoking-related increase in intimal thickness in the kidney. Past studies implicating smoking as a factor in myocardial intimal proliferation are confirmed by this investigation. Further work needs to be done on age-related changes.

ACKNOWLEDGEMENTS

I am greatly indebted to Dr. Henry R. Black for his unfailing patience and accessibility while directing this study.

I give many thanks to Dr. Walker Smith for his technical assistance and numerous helpful comments.

My heartfelt thanks to Mr. Leo Kelly and Ms. Agatha Daley without whose technical assistance this study could not have been done.

Above all, my gratitude to D. A. B. for her patience, helpful commentary, and unfailing support.

INTRODUCTION

Cigarette smoking has been implicated as a major risk factor in increasing the mortality from a variety of disease entities (1,2,3). In conjunction with the mounting evidence for the role of smoking in the etiology of several neoplastic disorders, several anatomical studies have focused on the non-neoplastic effects of cigarette smoke (4,5,6,7,8,9). The most frequently observed response is an increase in fibroelastic intimal proliferation and hyaline thickening in the intima of vessels of smokers. Similar and supposedly idiopathic or age-related vascular changes have been noted in the renal vessels (10,11,12). Histologically, the alleged age-related phenomena noted in the kidney resemble those changes seen in the vessels of long-time smokers, i.e., hyaline arteriolar thickening and fibroelastic proliferation. Since none of the anatomical studies which describe age-related changes have taken smoking into account, the arterial effects attributed to aging might reflect the peripheral effects of cigarette smoking.

Renal function has been noted to decline with age in the absence of overt pathological processes. It is estimated that the glomerular filtration rate declines an average one percent per year after age 40 (13). This is reflected in the need to reduce what is considered a normal creatinine clearance

with aging and at least one linear relationship has been proposed as an age-adjusted estimate (14). In addition, the aged kidney's capacity to secrete p-aminohippurate or to handle an acid-base load is compromised (15,16,17).

In conjunction with the functional declines noted with age, there are a number of histological changes which occur. Rosen describes a number of degenerative events in the aging kidney (18). There are striking changes in the tubules with tubular collapse and atrophy as well as widespread fibrosis and hyalinization of glomeruli. Several studies focus on the effects of aging on the renal vasculature.

Atherosclerotic plaques have long been described in the aorta and coronary arteries. Renal arteries reflect these changes to some extent and arteries down to the size of the arcuate vessels show atherosclerotic changes consisting of fibrous thickening of the intima with reduction in the luminal area. However, intimal lipid as seen in classic lesions in the aorta are not present. Smaller arteries, such as the interlobular arteries, show fibroelastic thickening with reduplication of the internal elastic lamina. The smallest arteries and the arterioles develop hyaline thickening of the intimal and subintimal structures with marked luminal narrowing. Both diabetes mellitus and systemic hypertension can accelerate the severity and frequency of all of these lesions, but the progression of the lesions in all three sizes of arteries can be shown to be a function of aging in normotensive, non-diabetics (10).

Moritz et al. (11) and Bell (12) have described similar lesions in non-hypertensive patients and shown a correlation with age. Intimal thickening of the arterioles was never seen except in conjunction with fibroelastic changes in the small arteries and as such was taken as evidence that arteriolar lesions reflected systemic vascular disease.

These vascular changes are reflected in dynamic studies which attempt to chart renal blood flow in the aging kidney. Cortical arteriolosclerosis was described with a subsequent shift in blood flow to the juxtamedullary glomeruli and medullary vessels (19). In addition studies utilizing radioisotope scans to chart perfusion distribution show focal areas of diminished uptake in elderly patients with no evidence of renal disease. It is suggested that in these elderly patients, focal vascular insufficiency might account for the findings (20).

Cigarette smoking has been identified as a risk factor in cardiovascular disease (1,2,3,21) and most conclusively in coronary artery disease (22,23). This fact led several groups to attempt to define the histological correlates of the observed epidemiological phenomena. Auerbach et al. were among the first to look at small vessel changes in smokers.

All three studies by Auerbach (4,6,7) had essentially the same experimental technique. Autopsy material from various organs were stained with hematoxylin and eosin and elastica van Gieson stains. One observer scored the slides for the

grade of thickening of the vascular walls without prior knowledge of the smoking history. Results were expressed as the percentage of subjects in each age category with moderate to advanced lesions. Auerbach found that for heart, lung, esophagus, adrenal and pancreas, the percentage of subjects with advanced fibrosis or hyaline thickening was greater among smokers. No kidney sections were examined in these studies.

The studies rely exclusively on the qualitative observations of a single observer. Also, the data does not lend itself to statistical analysis making it difficult to judge its significance or reproducibility. However, the results are suggestive of intimal involvement as a function of cigarette smoking.

The other major study in this area focused mainly on the arteriolar medial area. Naeye (8) used the point counting method of Chalkley (24) to measure the medial area as a ratio of media to the average area of the intimal nuclei per arteriole. The latter measurement was used as an internal standard to correct for dilatation and sectioning artifact.

Naeye proposed that the decrease in medial area from sub-epicardial to sub-endocardial arteries was based on a decreasing perfusion pressure gradient. This gradient was felt to be a consequence of sub-epicardial intimal proliferative lesions, which decreased downstream perfusion. Percentage decreases in medial area were statistically greater in smokers.

While the data does suggest an effect of cigarette smoking, the proposed explanation for the phenomenon observed is still a matter of speculation. Naeye fails to examine the intima in detail except to note that sub-endocardial intimal lesions appeared in his youngest subjects and seemed to spread toward the epicardium with age. This fact taken together with his data suggests that, in fact, the actual lesion is not that of medial "atrophy" but rather damage and replacement by the intimal proliferative lesions.

The question of peripheral vascular damage as a significant consequence of cigarette smoking remains enigmatic. The attempt by Naeye to measure medial area represents the first attempt at utilizing reproducible techniques for measuring vascular wall components. However, past studies have implicated the intima as the target of cigarette smoke's vascular effects (5,25). As such, Naeye's paper did not directly address this issue.

This study will attempt to define the degree of intimal damage which may be associated with a history of cigarette smoking in autopsied subjects. Specifically, it will address the issue of renal microvascular changes as a function of smoking history and try to distinguish these effects from "aging" phenomena. Planimetric techniques will be applied to both renal and myocardial small arteries and arterioles in an attempt to develop reproducible and statistically analyzable data.

MATERIALS AND METHODS

Patient Sample

Subjects for this study were selected from two groups of autopsied patients. The first, consisted of all patients autopsied at the West Haven Veteran's Administration Hospital between March and November, 1978. There were, initially, 50 patients available from this group. To augment the population of non-smokers available for analysis, the records of Yale-New Haven Hospital were examined for all non-smokers autopsied between January and December 1978. Fifty-two names were submitted for screening.

Reasons for exclusion from the study included: lack of sufficient available medical history or inadequate smoking history, documented hypertension or repeated blood pressures of 160/90 or greater. Documented diabetes mellitus or repeatedly elevated serum glucose levels of 160 mg% or greater, collagen-vascular disorders, angitides, gout, chronic aspirin ingestion, chronic pyelonephritis, chronic renal failure, severe and symptomatic obstructive uropathy and acute renal failure from any cause other than acute tubular necrosis were all reasons for exclusion from this study. (See Table 1 for summary.)

Of the 50 subjects available from the Veteran's Hospital, 31 were not excluded. This group consists of 21

smokers, 4 ex-smokers and 6 non-smokers. Ages ranged from 31 to 90 years old. Of the patients screened at Yale-New Haven, 9 patients were included in the study including 4 males and 5 females. Ages ranged from 26 to 83 years.

Section Analysis

Sections were obtained as follows: One section from the left ventricular free-wall was taken from each subject. Care was taken to obtain transmural sections in all cases. Renal slides were obtained from standard autopsy sections and included both cortex and medulla. All sections were stained with elastica van Gieson stain. This technique emphasizes both internal and external elastic lamina allowing for easier recognition of wall structures.

Each slide was assigned a random number using a standard random number table. All measurements were carried out on the slides without knowledge of the autopsy number or smoking history. One myocardial and one renal section was examined for each patient.

Planimetric analysis was used to measure the degree of intimal proliferation in the arteries. Only vessels cut in cross-section or at a shallow tangential angle were analyzed. Longitudinally cut arteries or those obviously damaged by preparation techniques were excluded. The number of arteries and arterioles used for analysis per section ranged from 2 to 12. Random sampling of arteries was maintained by analyzing every possible artery in a section. Acceptable arteries ranged in size from approximately 25μ to 550μ (Table 1).

Each artery to be measured was photographed at the highest magnification which would allow inclusion of the whole vessel. The magnification used was noted for each artery photographed in order to compute and compare vessel sizes.

The following measurements were made on each vessel. Using a Kontron MOP/AM01 planimeter, the area of the lumen (L), lumen plus intima (I), and whole vessel (M) were measured. To measure I, the internal elastic lamina was designated the outer limit of the intima. For vessels with fibro-elastic proliferation, the outermost elastic lamina not containing medial muscle cells was so designated. In vessels too small to have an external elastic lamina, the outer edge of the medial muscle was considered the outer limit of the artery or arteriole. All area results were recorded in millimeters squared (mm^2) and diameters were first measured in millimeters and then divided by the magnification of the photograph to obtain the true vessel diameter. This method of measuring the diameter cannot account for tissue shrinkage secondary to fixation nor for severe vessel dilatation. Only two broad categories of arteries, i.e., greater or less than 150μ , will be compared, so that minor changes in diameter due to fixation artifact will not change the conclusions.

The tangentiality of the plane of section to the vessels changes their apparent size. The narrowest diameter was measured, since it most closely approximates the true diameter of the vessel. No corrective measures are needed

for vessel wall components since all comparisons are in terms of ratios of the wall components. These ratios are unaffected by the tangentiality because each component has its area changed by the same factor.

In order to derive the percentage contribution of the intima to the total wall area, the lumen area (L) was subtracted from the composite areas I and M.

Therefore, the area of the intima is the area of the intima plus lumen (I) minus the lumen area (L):

$$\text{Intimal area} = I - L$$

The area of the vascular wall is calculated from the whole vessel area (M) minus the lumen area (L):

$$\text{Vessel wall area} = M - L$$

The ratio, therefore, of the intima to the vessel wall or the relative contribution of the intima is:

$$\% \text{ Intima } (\% \text{int.}) = I - L / M - L$$

This value is independent of the magnification of the photograph since the units (mm^2) cancel out. Interartery comparisons can be carried out using % int. values without further correction. Therefore, this value was derived for every vessel photographed and recorded for analysis.

Statistical Analysis

Subjects were categorized by age and smoking habit. Four major groups resulted. Smokers were divided into an

older group with ages ranging from 60-90 and a younger group less than 60 years old. Non-smokers were divided in a similar fashion. Two tissue types, myocardium and kidney, were evaluated in every group.

The average value for % intima (AVG.) was calculated and recorded for each tissue type in every patient. Since a majority of sections (79%) had vessels both greater and less than 150μ in diameter, the average % intimal value for small vessel (less than 150μ) and larger vessels (150μ or greater) were also calculated for each section analyzed.

Means and variances for each size artery (AVG., $<150\mu$, and $>150\mu$) in myocardium and kidney were calculated for each of the four major groups mentioned above (Table 2). A Bartlett's test of homogeneity of variance showed no significant difference in the intergroup variance. Therefore, the student t-test was utilized to compare mean values. The following comparisons were made:

Comparison 1: Smokers versus Non-smokers (Tables 3-12)

A. All smokers v. all non-smokers--For each tissue type, each arterial size class in smokers was compared to its counterpart in the non-smoking population. Smoker means were compared both with and without the values for the four (4) ex-smokers.

B. Smokers ≥ 60 y.o. versus non-smokers ≥ 60 y.o.--For each tissue type (myocardium and kidney), each arterial size class in smokers ≥ 60 were compared to the same size class in non-smokers ≥ 60 . Smoker %

intima means were calculated and compared both with and without the values for the four ex-smokers.

C. Smokers < 60 y.o. versus non-smokers < 60 y.o.--

For each tissue type, each arterial size class in smokers < 60 y.o. were compared to the same size class in non-smokers < 60 y.o. There were no ex-smokers in this latter group.

D. Cross-correlations--Similar calculations were made using the following groups: Smokers ≥ 60 y.o. versus non-smokers < 60 y.o. were compared by tissue type and arterial size class; smokers < 60 y.o. versus non-smokers ≥ 60 y.o. were similarly compared.

Comparison 2: Small Vessel (<150 μ) versus Large Vessel (>150 μ) (Tables 13-16)

A. Smokers--This group was broken down into ages ≥ 60 y.o. and < 60 y.o. Within each tissue type, small vessels were compared to large vessels by comparing the mean for each size class. For the group ≥ 60 y.o., values were compared both with and without the ex-smokers.

B. Non-smokers--The same calculations were carried out on this group as in 3A.

For all calculations, P values of 0.05 or less were considered significant. For all values of $P > 0.05$, Type II error analysis was calculated to avoid an inappropriate acceptance of the null hypothesis. The value of β is the probability of accepting the null hypothesis when it is, in fact, false (43). Unlike the calculation of the standard P

value, β is based on a non-zero difference between means (D). The choice of D is empirical and usually based on past investigations or observations. For the purposes of this study, no such past observations exist and values for D were chosen from minimum significant differences of 0.07 to a maximum of 0.15.

Finally, linear regression analyses were calculated in an attempt to establish a relationship between % int. values and 1) smoking history as either packs per day or pack-years and 2) age.

TABLE 1

EXCLUSION CRITERIA

- Patients -
- 1) Lack of sufficient medical history
 - 2) Lack of or inadequate smoking history
 - 3) Documented diastolic hypertension
 - 4) Repeated blood pressures of 160/90 or greater
 - 5) Documented diabetes mellitus
 - 6) Repeatedly elevated serum glucose of 160 mg% or elevated fasting blood sugar
 - 7) Collagen-vascular disorders
 - 8) Angiitides, e.g., Buerger's disease
 - 9) Gout
 - 10) Chronic aspirin ingestion
 - 11) Chronic pyelonephritis
 - 12) Chronic renal failure
 - 13) Severe and symptomatic obstructive uropathy
 - 14) Acute renal failure--from any cause other than acute tubular necrosis
- Arteries -
- 1) Vessels cut in a longitudinal plane
 - 2) Vessels damaged by preparation techniques
 - 3) Vessels greater than approximately 600 μ .
 - 4) All epicardial vessels

RESULTS

The raw data is listed in Appendix I. Table 2 contains the % intima values for each patient with the mean, standard deviation and variance for each subgroup. Tables 3-20 detail the results of the various comparisons. Calculations were done both with and without the four ex-smokers in this study. Since removal of these four subjects did not alter the significance of the data, they were included in all reported results.

Smokers versus Non-smokers

Myocardium

A comparison of all smokers against all non-smokers, regardless of age, reveals a highly significant increase in the % intima in smokers (0.50 ± 0.07 -AVG.) over non-smokers (0.31 ± 0.08 -AVG.) with $P < 0.001$ (Table 3). For each arterial size class, the relative contribution of the intima to the whole vessel area is similarly significantly increased in smokers ($P < 0.05$ to $P < 0.001$).

For smokers older than 60, comparison to age-matched controls yields the same relationship. Smokers (0.41 ± 0.06 -AVG.) show an increase in % intima over non-smokers (0.33 ± 0.08 -AVG.) which is highly significant ($P < 0.02$), (Table 5).

For smokers under age 60, comparison to age-matched

controls yields similar relationships (Table 7). The increase in % intimal area in smokers is significant for the average (smokers- 0.38 ± 0.09 ; non-smokers- 0.29 ± 0.07 ; $P < 0.05$) % int. and for arterioles $< 150\mu$ (smokers 0.41 ± 0.10 ; non-smokers- 0.29 ± 0.08 ; $P < 0.02$). Vessels $> 150\mu$ show an insignificant difference ($P < 0.30$). However, β analysis indicates that a significant difference cannot be ruled out. A larger N would clarify this uncertainty.

Comparison of smokers ≥ 60 years old (0.41 ± 0.06 -AVG.) versus non-smokers < 60 (0.29 ± 0.07 -AVG.) shows a highly significant increase ($P < 0.001$). This relationship holds for all vessel sizes examined (Table 9).

Comparison of smokers < 60 y.o. (0.38 ± 0.09 -AVG.) versus non-smokers > 60 (0.33 ± 0.08 -AVG.) shows some statistical uncertainty ($P < 0.30$, $\beta > 0.10$). A significant difference cannot be ruled out in AVG. or the $< 150\mu$ groups. However, a comparison of the vessels $> 150\mu$ for these age groups show younger smokers (0.31 ± 0.07) have a significantly greater % intima than older non-smokers (0.21 ± 0.02) at $P < 0.05$ (Table 11).

Kidney

A comparison of all smokers against all non-smokers, regardless of age, reveals a highly significant increase in the % intima in smokers (0.46 ± 0.07 -AVG.) over non-smokers (0.34 ± 0.09 -AVG.) with $P < 0.001$ (Table 4). For each arterial size class, the relative contribution of the intima to the whole vessel area is similarly significantly increased in smokers ($P < 0.001$).

For smokers older than 60, comparison to age-matched controls yields the same relationship. Smokers (0.47 ± 0.05 -AVG.) show an increase in % intima over non-smokers (0.37 ± 0.07 -AVG.) which is significant ($P < 0.01$), (Table 6). Similar calculations on vessels $< 150\mu$ are significant ($P < 0.05$). Again, vessels $> 150\mu$ in diameter had % intima difference which was insignificant ($P < 0.10$). β analysis of this data indicates that a significant difference can not be ruled out. A larger N would clarify this uncertainty.

For smokers under age 60, comparison to age-matched controls yields similar relationships (Table 8). Smokers (0.44 ± 0.10 -AVG.) show an increase in % intima over non-smokers (0.32 ± 0.10) which is significant ($P < 0.02$). This relationship also exists for vessels $< 150\mu$ and $> 150\mu$ at $P < 0.02$ and < 0.05 , respectively.

Comparison of smokers ≥ 60 y.o. (0.47 ± 0.05 -AVG.) versus non-smokers < 60 y.o. (0.32 ± 0.10 -AVG.) was highly significant ($P < 0.001$) for all vessels examined (Table 10).

Comparison of younger smokers < 60 y.o. (0.44 ± 0.10 -AVG.) with older non-smokers ≥ 60 (0.37 ± 0.07 -AVG.) shows the difference to be insignificant ($P < 0.20$). Similar results were obtained when each vessel size class was examined. β analysis indicated that a significant difference could not be ruled out in any of the size classes (Table 12).

Small Vessels versus Large Vessels

Myocardium

For smokers ≥ 60 y.o., comparison of small (0.46 ± 0.08)

versus large vessels (0.31 ± 0.06) indicates that the % intima is statistically greater in small vessels ($P < 0.001$), (Table 13).

For smokers less than 60 years old, small vessels have a greater % intima at $P < 0.05$ (Table 13).

For non-smokers ≥ 60 y.o., comparison of small (0.29 ± 0.04) versus large vessels (0.21 ± 0.02) indicates that the % intima is greater in small vessels ($P < 0.05$), (Table 15). However, for non-smokers less than 60 y.o., there was no significant difference with a $P < 0.40$ and $\beta < 0.10$ (Table 15).

Kidney

For smokers ≥ 60 y.o., large vessels (0.51 ± 0.08) had a greater % intima than small vessels (0.44 ± 0.09) at a $P < 0.05$ (Table 14). Non-smokers, in the same group, show similar results ($P < 0.05$), (Table 16).

For smokers less than 60 y.o., small vessels (0.44 ± 0.12) were compared to large vessels (0.47 ± 0.09), (Table 14) and the difference was not significant ($P < 0.20$). Non-smokers, in the same group, also show no significant difference ($P < 0.20$), (Table 16).

Age Comparison

Myocardium

Comparison of smokers ≥ 60 y.o. (0.41 ± 0.06 -AVG.) with smokers < 60 y.o. (0.38 ± 0.09 -AVG.) showed no significant difference ($P < 0.50$), (Table 17). Vessels $> 150\mu$ also showed no difference ($P < 0.90$). However, vessels $< 150\mu$ had a possible significant difference by β analysis.

In non-smokers, comparison by age showed more uncertainty and a larger N would be required to define the significance of any difference (Table 19).

Kidney

Comparison of smokers ≥ 60 y.o. (0.47 ± 0.05 -AVG.) with smokers < 60 y.o. (0.44 ± 0.10 -AVG.) showed no significant difference ($P < 0.30$). Vessels $< 150\mu$ also showed no difference ($P < 0.90$). However, vessels $> 150\mu$ showed more uncertainty ($P < 0.10$) since β analysis indicated that a significant difference could not be ruled out (Table 18).

Non-smokers in the kidney, like the results for myocardium, show greater uncertainty. Comparison of older subjects (0.37 ± 0.07 -AVG.) versus younger ones (0.32 ± 0.10 -AVG.) are not, strictly defined, significant ($P < 0.20$). Vessels $< 150\mu$ and $> 150\mu$ also showed P values > 0.05 . β analysis of all three groups indicates that a significant difference can not be ruled out (Table 20).

Linear Regression Analysis

Percent intima values in each vessel size class were compared against 1) smoking history both as packs per day and as pack-years, and 2) ages of subjects. No significant relationships could be established among the multiple categories examined by this method.

TABLE 2

| Group | Subject | Age | Smoking History | Myocardium - % int. | | Kidney - % int. | | | |

DISCUSSION

Cigarette use, and tobacco use in general, have long been the subject of serious and often heated debate. Since the 16th century when it was first introduced to Western man, tobacco has been extolled as medicinal and vilified as being, at best, a loathsome custom (21). Despite the condemnation leveled against its use, the amount and frequency of tobacco usage has increased steadily.

Until the early 1900's, the major forms of tobacco consumption consisted of pipe and cigar smoking, and chewing tobacco. In the year 1900, of the total of 7.43 pounds of tobacco used per person, a full 4.1 pounds were consumed as chewing tobacco and 1.6 pounds as pipe tobacco (26). In that year the per capita cigarette consumption was a meager 49. This relationship changed rapidly over the ensuing decades. While tobacco use in general increased and reached a level of approximately 11 pounds per person per year by 1960, the amount of pipe tobacco, cigars and chewing tobacco used decreased by at least 50% in that time. The decrease in these products was offset by a dramatic increase in cigarette use. From an average 49 cigarettes per capita in 1900, the consumption of cigarettes rose to almost 4,000 cigarettes for every adult American over the age of 15 years by 1960 (26).

In the early 1900's, statisticians first noted disturbing trends among tobacco users. There were indications that this group suffered from such diverse disease entities as lung cancer, cardiac and non-cardiac vascular disorders and non-neoplastic respiratory disease more often than their non-smoking counterparts (21). This data, like the many retrospective studies which followed, was often criticised on several points. As in any retrospective study, especially one using mortality as an endpoint, inaccurate data from secondary sources and selection bias are difficult to avoid. The compilation of retrospective data necessitates assumptions about the relationship between the investigated topic and the suspected causative factors. As such, the data may also suggest that smoking may only represent a marker of some other quality or habit which would predispose to one or more of the above diseases.

In the early 1950's, Doll and Hill published the first prospective analysis of the risk of lung cancer and other diseases as a function of smoking habit (1). This study was able to statistically link cigarette smoking among British doctors with their deaths from lung cancer and "coronary thrombosis." These two entities showed the strongest correlation, but non-neoplastic respiratory diseases also showed some linkage with smoking history. In addition, they were able to demonstrate a gradation of mortality ratios based on the extent of tobacco use.

Hammond and Horn reported, in a 44-month follow-up

study of 188,000 men, that mortality rates were higher in smokers. Of 11,870 men who died in this time, 4,406 occurred among men with a history of regular cigarette smoking only. Only 2,623 of these men would have died had their age-specific death rates been the same as for non-smokers in this population. The mortality ratio is then 1.7. These statistics were also broken down by disease category. For lung cancer, the mortality ratio for smokers was 10.73 and for all heart and circulatory diseases 1.57. Coronary artery disease was the cause of death 1.7 times as often in smokers. Hypertension was not associated with an increased mortality in smokers and generalized arteriosclerosis showed only a modest, statistically insignificant rise in smokers. In diseases which showed a correlation with smoking, heavy smokers suffered more often than light or occasional smokers (2).

Subsequently other reports demonstrated a correlation between cigarette smoking and mortality rates. In all, seven studies showed, in a prospective fashion, the serious epidemiological outcome of cigarette use and formed the basis of the arguments presented in the 1964 report to the Surgeon General of the U.S. Public Health Service (21). A recent update of the Surgeon General's report reconfirms these findings and extends the results, previously lacking evidence, to women (27). Finally, a recent article by Friedman et al. (28) assessed the relation of cigarette smoking to mortality in an 11-year follow-up study of 4,004 men and women.

Multivariate analysis showed a consistent correlation between smoking and mortality from all causes and most strikingly with coronary artery disease.

Other studies solidified the association between cigarette use and deaths due to cardiovascular disease. The most striking association remained the relationship between smoking and myocardial infarction (22,29,30,31,32,33). This link was of higher reliability than for angina pectoris which was either weakly linked (34,35) or not linked at all (23).

Auerbach et al. became interested in the pathological effects which might relate to cigarette use and the changes associated with constant exposure to smoke. The preliminary report by his group in 1957 (36) indicated that the frequency of carcinoma in situ, squamous metaplasia, stratification and basal cell hyperplasia was increased in smokers. The full study (37) consisted of 402 white males with reliable smoking histories. From each subject, 55 areas of the tracheo-bronchial tree were examined microscopically without prior knowledge of the smoking history. The most striking lesion observed, other than invasive carcinoma, was areas showing increased numbers of atypical cells with absent cilia. This lesion was never found in non-smokers, but was present in 4.3% of sections from smokers of 1-2 packs per day; 11.4% of sections from those smoking 2 or more packs per day and in 15% of these sections obtained from patients succumbing to lung cancer.

The demonstration of specific pathological changes, which were statistically linked to the amount and frequency of cigarette use, was the basis of efforts to elucidate other local changes in the lung. One such study linked vascular changes in the lungs of rats exposed to cigarette smoke (38). This led Auerbach et al. to consider the effects smoking might have on the lung parenchyma and vasculature in humans. A study was undertaken between 1955 and 1960 on 1582 autopsied males (39). Histologic slides were scored blindly and in random number order. The following pathological changes were rated by one observer using a scaled grading system of 0 to 3 or 4. Zero was normal and ratings of 3-4 indicated advanced changes. Four areas of each slide were averaged and in a preliminary study of 242 subjects, the agreement between first and second readings was 0.90. Pathological changes observed were rupture of alveolar septa, fibrosis, thickening or attachments to the septa and thickening of the walls of arteries and arterioles.

The results indicated several interesting items. First, there was no significant difference, for any of the changes, between smokers by race when matched for age and smoking history. All changes were closely allied to age and cigarette smoking. Among men of the same age, non-smokers showed far less changes than light smokers. Light smokers (1 pack per day) showed far less change than heavy smokers (2 packs per day or greater). Ex-smokers who had not smoked for at least three years prior to death showed less change

than equivalent smokers who had continued smoking up to the time of their terminal event. Strikingly, non-smokers over age seventy had far less pulmonary parenchymal and vascular injury than smokers less than forty-five years old.

Two alternate theories were proposed to explain the tissue response to cigarette smoke seen in the lung. The first is that these effects are simply a result of irritant factors in the smoke acting locally on the lung parenchyma. The other possible explanation is that the pathological changes noted are the pulmonary manifestations of a more generalized systemic effect of some ingredient in the inhaled smoke. This latter theory was enticing in the face of all the epidemiological data linking smoking to disease in a variety of organ systems.

The first of two studies designed to elucidate the systemic effects was published in 1968 (4). Again, looking at small artery and arteriolar changes as a marker of the effect of smoking on tissue, five types of tissue were examined for "fibrous thickening" of the small arteries and arterioles. Thickening was measured on a qualitative grading scheme of 0-3 for arterioles and 0-2 for small arteries and all sections were examined by one observer. As in the other studies, slides were scored without knowledge of the smoking history and in random order. Tissues examined included trachea and main-stem bronchi, esophagus, stomach wall, pancreas, and adrenal gland. Of these, the latter two have no chance of having had direct contact with cigarette smoke and could

only have been affected by substances carried via a hemogenous route. No samples from kidney were examined.

The results were expressed as "more than a slight degree," i.e., greater than grade 1 degree, of fibrous thickening as determined by the average reading per patient. The findings, standardized for age, indicated that the percentage of subjects with abnormal readings increased with the amount of cigarettes consumed per day. This was true for all tissues examined. There was, however, no attempt to correlate individual smoking history with the extent of thickening of vessels in that subject.

During this time, it was shown that various toxins can affect the myocardial vasculature. One study (25) reported that denicotinized tobacco proteins given to rabbits apparently caused a thickening of the walls of the small arteries in the myocardium. This was felt to be on an "allergic" basis. Another mechanism for the systemic effects of cigarette smoking invoked the presence of high concentrations of carbon monoxide in smoke. Wanstrup et al. (5) exposed rabbits to modest levels of carbon monoxide for three months and then examined aortas for signs of damage. In those rabbits exposed to carbon monoxide, there were focal degenerative and "reparative" intimal changes which were present in a significantly higher percentage than in controls. These findings were felt to strengthen the case for a systemic effect of tobacco smoke.

The extent to which the myocardial vasculature in humans reflect these supposed systemic effects was addressed

by a study published in 1970. Auerbach et al. studied both beagle dogs, trained to smoke, and human smokers with post-mortem examinations (6). In the human study, 746 men with known smoking histories were examined. Three slides were taken from each subject, one each from right ventricle, interventricular septum and the left ventricular free wall. As before, the randomized slides were qualitatively graded by one observer. All arterioles in a section were examined and a slide was assigned a grade on the basis of the thickest arteriole seen. The extent of agreement between areas of the myocardium within a given subject seemed to rule out a local effect as a cause of arteriolar thickening.

The grade or degree of thickness rose with advancing age when the subjects were standardized by smoking history. This agreed with past studies on other organs. By age group, the degree of wall thickness was greater among smokers over their non-smoking counterparts. Again, in the smoking group, the grade of arteriolar thickening showed an increase with the amount of cigarettes consumed. Here, as in the past, criticism rests on two points. First, the data is not subjected to statistical analysis for the validity of the trends cited. In addition, the use of only one observer assigning qualitative grading values fails to address the issue of reproducibility.

The two studies on beagle dogs taught to smoke showed results similar to past studies on human subjects. Two additional pieces of information emerged from the data. First,

there was a difference in arteriolar thickening based on whether the dogs smoked filtered or non-filtered cigarettes, with non-filtered cigarettes causing greater damage. Since filters do not affect the carbon monoxide level in smoke (21), this data argued against Wanstrup's thesis that carbon monoxide was the major cause of vascular damage. The second finding related duration of smoking to an increase in apparent vascular damage. The studies on dogs suffer from the same shortcomings as the human portion of this study and the data must be assessed with that in mind.

Further investigation by Auerbach led to the most recent paper in 1976 (7) which used his previous technique to look at both large and small vessel disease as a function of smoking history. Since several studies had shown the relationship of coronary and aortic atherosclerosis with cigarette smoking (40,41), this present study was constructed to examine the coronary arterial system on both macro- and microscopic levels.

The macroscopic and microscopic coronary artery findings in this study were similar to previous findings of increased coronary atherosclerosis and fibrous intimal thickening in smokers. In fact, fibrous thickening was absent in 60.6% of men under 65 who had never smoked regularly. However, in the same age group, fibrous intimal thickening was absent in less than one percent of those smoking one pack per day or more.

As in the coronary artery portion, the intramyocardial arteries and arterioles were examined for fibrous intimal

thickening. In addition, arterioles were examined for hyaline thickening of the intima following observations of similar lesions in beagle dogs tracheostomized and trained to smoke cigarettes. An attempt was made to exclude disease entities either associated with known vascular sequelae or likely to introduce bias into the study and, therefore, subjects with diabetes mellitus, fatal coronary artery disease and those with heart weights greater than 500 gm. were excluded.

Findings in this 1976 study confirmed past studies to the extent that moderate to advanced thickening was present in 60-70% of smokers using greater than one pack per day. In those who never smoked regularly, the same changes were noted in only 0 to 0.4% of subjects. Strikingly, hyaline arteriolar thickening was noted in 97-98% of those smoking greater than one pack per day. No subject was noted to have such arteriolar lesions if they had never smoked regularly. While this data is extremely suggestive, no statistical analysis was done to attest to its validity.

Since the publication of the above study, two additional studies have been reported which, in part, address some of the reservations mentioned above. Specifically, both studies attempt to measure proliferative lesions or their consequences by some objective means.

The first of these, by Naeye et al. (8), introduces several new aspects to this area of investigation. This study attempts to show that proliferative lesions in sub-epicardial vessels, because they decrease perfusion pressure distally, actually cause a decrease or "atrophy" in arteriolar muscle

mass in the sub-endocardial vessels. The proposed mechanism is based on studies which show that arteriolar medial muscle mass reflects perfusion pressure. The paper attempts to demonstrate the relationship of sub-endocardial ischemia to sub-epicardial intra-myocardial lesions.

One of the contributions this paper makes to this field of investigation is an attempt to screen subjects for, and exclude them on the basis of, systemic disorders with known vascular sequelae. In addition to diabetes mellitus excluded by Auerbach, hypertension, hypertrophic cardiomyopathy from any cause, transmural infarctions and "collagen disorders" were all reasons for exclusion.

The most important contribution of this work, was the application of microscopic area measurement techniques to analyze the arterioles. The point counting method first described by Chalkley (24) was used to measure the area of arteriolar media and all values were expressed as the area of the media to the average area of intimal nuclei per arteriole. The latter value was used as an internal standard to correct for dilatation and artifacts produced in sectioning. The use of area measurement eliminated the criticism of one-observer bias by using quantitative data.

Naeye examined arteries from 34 non-smokers (13 women and 21 men) and 43 smokers (16 women and 27 men). Consecutive autopsies were used as much as possible. The results purport to show a decrease in arteriolar medial muscle mass from epi- to endocardium which was greater in smokers at P

values of 0.05 or less. However, the statement is made that proliferative intimal lesions appear in the sub-endocardial vessels at the youngest ages examined. With the age of the patient and smoking history these lesions appear to spread toward the epicardium. Thus, it is not clear whether the greater decrease in the media of the sub-endocardial vessels of smokers represents "atrophy" or instead a greater involvement with intimal and sub-intimal lesions. Although the explanation of the data is open to interpretation, the results do show quantitatively valid evidence of greater damage to the arteries of smokers.

Another approach to the problem of measuring the changes described by Auerbach et al. and the only study to include the kidney was that of Seez et al. (9). The arteries examined ranged in size from 300 to 500 μ in diameter and were examined by an intraocular scale at constant magnification. The thickness of the area of severest intimal thickening in an artery was measured and expressed as a fraction of the arterial diameter. The grading consisted of a six point system with normal equal to grade 1 which was less than 5% thickening. Each additional grade consisted of 5% increments.

Tissues examined included adrenals, brain, liver, lung, pancreas and kidney, but not myocardium. Of all tissues examined only lung was statistically linked to smoking history. Most other tissues showed a statistically insignificant trend in the same direction.

There are three major criticisms which can be leveled at this paper. First, this group did not mention what methods

and criteria were used to exclude patients with known vascular sequelae. In addition, the size of the arteries examined was much larger than those vessels felt to be most closely allied to smoking history in previous studies. This fact made comparison between studies more difficult. Lastly, the measurement process itself is open to question since observer selection of lesions could lead to considerable variability. For all these reasons, the question of whether the kidney reflects the smoking history of the patient requires further analysis.

The impetus for investigating the kidney microvasculature rests on studies which define an age related intimal change in renal vessels (10,11,12). It has been suggested that these vascular changes are responsible for both the steadily decreasing glomerular filtration rate with age (13,14), as well as, abnormalities in renal blood flow studies (19,20). These vascular changes are strikingly similar to those lesions thought to be related to cigarette smoking. In addition, the Kaiser-Permanente health group has shown a correlation between urinalysis abnormalities and smoking history (42).

The weight of evidence suggests a peripheral vascular response to cigarette smoking. However, most studies have not developed the data in a quantitative, easily reproducible form. Naeye used quantitative methods, but was interested solely in the arteriolar media and was not measuring those vascular lesions implicated by previous studies. The present

investigation focuses on the small arteries and arterioles in both myocardium and kidney using planimetric analysis.

The myocardial vessels in smokers show a highly significant increase in intimal thickness in all arterioles examined ($P < 0.001$). This was true for all smokers when compared to non-smokers and when compared in age-matched groups.

The degree to which cigarette smoke affects the small arteries and arterioles in the myocardium is demonstrated by several lines of evidence. First, larger arterioles ($> 150\mu$) in younger smokers were shown to have more intimal thickening than older non-smokers ($P < 0.05$). Smaller arterioles in smokers show similar changes but without the same statistical confidence. This data confirms past observations by Auerbach and argues to the significant effect of cigarette smoke on younger patients.

A demonstration of the dramatic effect of smoke on small vessels results from comparison of small versus large vessels within age and smoking groups. Non-smokers older than 60 show greater intimal proliferation in their small arterioles ($P < 0.05$). However, younger non-smokers show no significant difference between vessel size. This age related change in small vessel proliferative lesions is not seen in smokers since both groups show significant small vessel intimal changes. This argues, as did the previous data, that younger smokers show striking changes over their non-smoking counterparts.

Age changes were not well demonstrated when groups were controlled for smoking history. This may be explained in either of two ways. If the age changes noted in past studies are valid then perhaps this study had too few subjects to demonstrate such an effect. Type II error analysis suggests that this is true. Alternatively, there may be few if any small vessel changes with age. A larger group of subjects would clarify this point.

All of the smokers in this study had at least a one pack per day smoking habit. The relatively narrow difference between the reported smoking habits may explain the lack of correlation between the amount smoked and the extent of intimal proliferation. There were too few ex-smokers to reliably draw conclusions about this group.

Renal arterioles in smokers show a highly significant increase in intimal thickness for all vessels examined ($P < 0.001$). This was true of all smokers when compared to all non-smokers and when compared in age-matched groups. This represents the first confirmation of the significant effect of smoking on the renal vessels.

Examination of the relationship of small vessel intimal fibrous proliferation to larger vessels shows results quite different from that of the myocardium. In the kidney, both younger smokers and non-smokers show no significant difference. However, with increasing age, larger vessels show greater intimal thickening than small vessels. Thus there seems to be an age related increase in larger arteriole intimal proliferation which confirms past reports and is distinct from the effect of smoking.

Age comparison by smoking group for each arteriole size class is inconclusive and requires larger numbers of subjects. In the face of the preceding data, an age related change can be confidently stated. Examination of ex-smokers and regression analysis using smoking history and intimal proliferation all require larger numbers of subjects.

Conclusion

There are three major conclusions resulting from this study. First, cigarette smoking is highly associated with both renal and myocardial arteriolar intimal damage. This study is, therefore, the first confirmation of the effect of cigarette smoking on the renal microvasculature. Secondly, small arterioles in the myocardium show the greatest change with time in smokers. There are measurable age related changes in both renal and myocardial arterioles, with renal arterioles showing the most conclusive association with age.

While the relationships defined are highly significant and support past epidemiological, as well as anatomical studies concerning cigarette smoking, this study cannot prove causality. However, unlike past studies, this investigation has been highly selective concerning the subject population and can, therefore, associate cigarette smoking alone with vascular damage with a high degree of confidence.

The exact relationship of intimal damage to age and the extent of smoking history requires larger numbers of subjects. Indeed, the implication that, at least for

myocardium, the smallest vessels are most affected by smoking by-products is intriguing and would be better defined by larger number of subjects.

The next portion of this investigation would focus on the exact relationship of intimal damage to renal function changes with age and especially smoking habit. The correlation of glomerular filtration rate, in the form of creatinine clearance, with the extent of arteriolar intimal damage in smokers might define at least a subgroup of patients whose renal function is adversely affected by cigarette smoking.
